

## The future of the Planet - Pollution & Climate Change

### Is the planet's health failing?

\n\n

\n

- The population of vertebrate species on Earth in the wild saw a dramatic fall of about 30% between 1970 and 2006.

\n

- This is due to destruction and degradation of natural habitats.

\n

- The freshwater ecosystems in the tropics are the worst affected.

\n

- The ecological footprint of humanity currently far exceeds the biological capacity of the earth to replenish it.

\n

\n\n

### What are the epochs that modern humanity has seen?

\n\n

\n

- Epoch is a geological time period that has a characteristic climate, life forms and other planetary features of its own. Ex: Jurassic

\n

\n\n

\n

- **Holocene** - For 12,000 after the last ice age, the Holocene epoch has offered a stable climate.

\n

- This was a period of grace for humanity to grow and flourish, with settlements, agriculture and lately economic and population expansion.

\n

- **Anthropocene** - Holocene has since morphed to a new epoch called anthropocene, the beginnings of which are being debated.

\n

- This epoch is marked by over-reliance on fossil fuels.

\n

- It also is an era of high industrial pollution, warming up of the planet and loss

of species.

\n

- Anthropocene has thus been defined as an age in which human activities will produce a significant impact on the planet's health.

\n

\n\n

## **Is a catastrophic collapse of the planet possible?**

\n\n

\n

- Many of the planet's systems respond in a non-linear manner and hence we usually don't see immediate proportional reactions to pollution, degradation and climate change.
- Some systems tend to see a sudden collapse if particular threshold levels are breached.
- When ecological tipping points are crossed, significant large-scale changes may occur - such as breakdown of glaciers, the loss of rainforests or failure of monsoons.
- Since systems interact with one another, crossing a threshold in one domain can influence another.
- For instance, greenhouse gas (GHG) emissions increase ocean acidification and land-use change often increases GHG emissions.
- Humans haven't yet understood many of these systems in detail and hence a sudden collapse is very much possible.
- Some experts opine that we are already at critical levels of concern for climate change, fresh water, species biodiversity and changes to nitrogen and phosphorus cycles.

\n

\n\n

## **How can the future be best approached?**

\n\n

\n

- Identifying interlinkages between biophysical planetary boundaries and development is essential to keeping the world safe by initiating

transformative changes.

\n

- While the future looks gloomy, the best we can do is to recognize sustainability as indispensable for survival and work towards the ideals framed in the 1992 Rio-Earth summit.
